## THE ACID-BASE CATALYSIS OF HYDROGEN ISOTOPE EXCHANGE REACTIONS

Following is the translation of an article by A. I. Shatenshteyn, Ye. N. Zvyagintseva, Ye. A. Yakoleva, Ye. A. Izrailevich, Ya. M. Varshavskiy, M. G. Lozhkina, and A. V. Vedeneyev entitled O Kislotno-osnovnom Katalize Reaktsiy Izotopnogo Obmena Bodoroda (The Acid-base Catalysis of Hydrogen Isotope Exchange Reactions) pages 218-233.<sup>7</sup>

### I. INTRODUCTION

When heavy water became available it was utilized for the study of acid-base catalysis. Comparison of the chemical reaction velocities, catalyzed by acids and bases in ordinary and heavy water, disclosed deceleration as well as acceleration of reactions in heavy water. The sign of the isotope effect indicates which stage of speed determines the kinetics reaction. With acid catalysis, such stages are: joining of proton (deuteron) to the reacting substance — subtraction and disintegration of the complex /1-5/.

Acids and bases catalyze the hydrogen isotope exchange reactions in substances dissolved in heavy water. There are many observations concerning homogeneous catalysis of the hydrogen exchange reactions. However, quantitative measurements of their velocity and activating energy are comparatively scarce /1-3/.

The area of hydrogen exchange reactions broadened when instead of heavy water other compounds of deuterium and new catalysts became available. Ingold and coworkers /6/ were first in accomplishing isotope exchange of hydrogen D<sub>2</sub>SO<sub>4</sub> and some saturated hydrocarbons. The study of the latter was offered by American authors (Burwell and Gordon, Beeck and Stevenson /7/) and by D. N. Kursanov jointly with V. N. Setkina /8/. Polaneyi with coworkers and Klit and Langseth /9/ discovered that the hydrogen exchange between C<sub>6</sub>H<sub>6</sub> and DCl in the presence of AlCl<sub>3</sub> occurs rapidly even at room temperature. Kharash with coworkers /10/ used C<sub>2</sub>H<sub>5</sub>OD for hydrogen exchange because organic substances dissolve better in it than in water. Brown /11/ accomplished some exchange reactions with

$\text{CH}_3\text{CO}_2\text{D}$  by means of sulfuric acid catalysis.

While studying hydrogen exchange in nonwater solutions, our laboratory at first used very strong bases and acids (for instance,  $\text{ND}_3$ ,  $\text{ND}_3+\text{ND}_2^-$ ,  $\text{DBr}$ ,  $\text{DBr}+\text{AlBr}_3$ ,  $\text{DF}$ ,  $\text{DF}+\text{BF}_3$ ). We calculated that this would result in deeper understanding of the type and of the rules governing these reactions and make clearer their mechanism; we also hoped to obtain new information on the reaction ability and acidity-basicity of organic compounds in connection with their structure and physical and chemical properties of the reacting medium. The results of the laboratory works were discussed in reviewed articles devoted to the mechanism of the hydrogen exchange in solutions /12/, reaction ability of organic substances /13/ and acidity-basicity of hydrocarbons /14/. This report on acid-basis catalysis of the hydrogen exchange reactions is a generalization of the results of mostly unpublished works conducted by Ye. N. Zvyagintseva, Ye. A. Yakovleva, Ye. A. Israilevich, Ya. M. Varshavskiy, M. G. Lozhkina, and A. V. Vedeneyev.\*

## 2. RULES OF ACID-BASIS CATALYSIS

While discussing acid-basis catalysis of hydrogen exchange reactions, we must first of all consider rules established for homogeneous catalysis in solutions /2/. Such is the well-known equation of Brønsted: the reaction velocity constant is proportional to the constant of the catalyster dissociation in a degree less than one,  $k=gK^a$ . Similar relationships describe the effect of changing force of the substratum as protolite at the assigned catalizer /15, 2/.

Upon catalysis by concentrated solutions of acids an equation of Hammett /16/ is usually observed: the logarithms of the reaction velocity constant are proportional to the function of the acidity of the acid  $H_0$ . The function  $H_0$  expresses the degree of ease of the proton transition to the uncharged molecule of the basis.

$$H_0 = - \frac{\lg K_{BH^+}}{c_B},$$

where  $K_B$  is a reaction equilibrium constant  $\text{BH}^+ \rightleftharpoons \text{B} + \text{H}^+$ ,

$$K_B = \frac{a_{\text{H}^+} \cdot a_{\text{B}}}{a_{\text{BH}^+}}.$$

\*The work was accomplished jointly with A. I. Shatenshteyn, who compiled this report.

Hine /17/ recorded the applicability of rules of general catalysis by bases to isotope hydrogen exchange between chloroform and water.

According to Beeck and Stevenson /18/, the Hammett rule is justified upon isotope exchange of hydrogen between isobutane and sulfuric acid, and Gold, Long, and Satchell /19/ substantiated it upon the exchange of hydrogen between anthracene and sulfuric acid of various concentrations, and also upon catalysis of sulfuric, hydrochloric, and phosphorus acids of the hydrogen exchange in benzene, p-nitrophenol and p-cresol.

In cases when we deal with solvents which are strong protolithic agents, the noted relationships of Brønsted is impossible to authenticate quantitatively in view of the absence of a dissociation constant for such systems. They can be conformed qualitatively. For instance, there is a parallelism between the velocity of the hydrogen exchange reactions, catalyzed by a solution of potassium amide in liquid deutoammonium, and the relative acidity of the hydrocarbons, expressed in a form of a conditional dissociation constant, determined by Conant and Wheland according to the degree of equilibrium displacement with participation of alkali-organic compounds /20, 21, 14/. The relative velocity of hydrogen exchange between hydrocarbons and the acid-solvents is comparable to the degree of basicity of the hydrocarbons, established by other means /14/.

For such solvents as liquid HBr and HF, and also solutions of  $\text{AlBr}_3$  in liquid HBr and of  $\text{BF}_3$  in liquid HF, the function of acidity was not determined and the authentication of the Hammett equation is as yet impossible.

The methods of comparison of alkalinity of strong bases are almost undeveloped. Upon catalysis with a base, the relationship of the base to proton (expressed in large calories) has importance, but the existing data is scarce; for instance, for the substances of interest to us, the following values were found:

For the noted reasons, it is necessary at this time to limit ourselves to qualitative discussion of results obtained with reference to homogenous catalysis of the exchange reactions in the mentioned solvents, though the results by themselves in the majority of cases are of a qualitative character.

### 3. PROPERTIES OF SOLVENTS

Table 1 contains protophilic, amphoteric, and protogenic solvents with which our laboratory conducted reactions of hydrogen exchange; it also contains the dielectric

constants (DP) and the dipole moments. The strongest base is placed at the top of the table and the strongest acid at the bottom of the table. In view of the lack of a practically useful single scale of acidity-basicity, it was necessary for us to be guided by constants of dissociation in water solutions ( $pK_{H_2O} = -\lg K_{H_2O}$ ). As to application to substances

themselves, this is not only conditional but also rather erroneous.

Of the amphoteric solvents, the table presents water and ethyl alcohol. Judging by some works /22, 23/, their acid-base properties are close but the ethyl alcohol is more acid than water.

Table 1  
Dielectric constants and dipole moments of studied solvents.

Solvent	$pK_{H_2O}$	Dielectric constant. $\mu \cdot 10^4$	
$NH_2CH_2CH_2NH_2$	4,0	14	1,94
$NH_2CH_2CH_2OH$	4,6	88	2,27
$NH_3$	4,7	16	1,46
$NH_2NH_2$	5,5	52	1,84
$H_2O$	—	80	1,84
$C_2H_5OH$	—	25	1,70
$CH_3COOH$	4,7	6	1,73
HF	8,2	80	1,91
HBr	— 9	4	0,79
HI	— 11	(8)	0,88

The DP role of the solvents in acid-base equilibrium and in catalysis is foreseen by Brønsted theory, in connection with the fact that this theory treats the acid-base interaction as a process of proton transition, calling in the case of electroneutral molecules for the formation of ions. It is natural that the latter must depend on the DP medium. However, it is now immediately clear that the Brønsted theory expresses a limiting condition of those processes which accompany acid-base interaction. Many facts /24, 25, 14/ allow us to conclude that the reactions between acids and bases proceed through a stage of polarized complexes, in which the reagents are connected by means of a hydrogen

bridge. Depending on conditions (among them the DP of the solvent) the reaction may stop at this stage or be completed by transition of the proton to the base and to formation of ions.

Table I also presents dipole moments of molecule solvents, inasmuch as their polarity must favor the emergence of noted complexes due to dipole interaction. In addition, the dipole solvent participate in solvation at the expense of energy which facilitates the rupture of molecules on ions. Participation of a solvent in the exchange reactions is made sharply apparent in the case of catalyses by ions (for example, by ions of  $C_2H_5O^-$ ) which are devoid of deuterium.

When we deal with various solvents and catalysts it is important to know how the velocity of isotope exchange changes during the transition from one solvent to another in the absence or with the addition of catalyst. It is desirable to compare the activity of one and the same catalyst in various solvents. The comparisons are handicapped by the fact that the hydrogen C-H -bands usually very slowly exchange with amphoteric solutions whereas the exchange velocity with basic and acid solvents in presence of catalyst occasionally is immensely great.

#### 4. COMPARISON OF DEUTEROEXCHANGE WITH AMPHOTERIC AND PROTOPHILIC SOLVENTS

In works of Ye. N. Zvyagintseva there is an attempt to estimate to what extent the velocity of the hydrogen exchange in the substances (in indene, acetophenone, methyl-naphthyl ketone) varies with amphoteric and protophilic solvents (deuteroalcohol or deuteroammonium) and, as was said, in both solvents (Table 2). Hydrogen exchange with alcohol even at  $120-150^\circ$  proceeds slower than with ammonia at  $0^\circ$ . Knowing approximately the activating energy of the isotope exchange in ammonium solution (for indene 12 kcal., for acetophenone 10 kcal.), we find that at identical temperatures the constants of the reaction velocities in both solvents differ by 4 to 6 orders. Such is the consequence of the great protophilic property of ammonia in comparison with alcohol.

We supposed that the ratio of the reaction velocity may change if the protolithic function of the substratum in each of the solvents is different. For verification we turned to the methylated nitrous heterocyclics- quinaldine and picoline, inasmuch as in alcohol solvent they are bases, and in ammonium - weak acids /26, 27/.

Experiments of Ye. N. Zvyagintseva indicated that hydrogen in methyl groups of quinaldine and  $\alpha$  picoline exchanges with alcohol even faster than with ammonia.

Table 2  
Velocity of the hydrogen exchange of some organic substances  
with deuteroalcohol and deuteroammonia.

— substance; 2-indene; 3-acetophenone; 4-methylnaphthyl estone; 5-fluorene; 6-quinaldine; 7-picoline.

Therefore, the relation of hydrogen velocities in two solvents depends not only on protolithic properties of these solvents but also on the structural peculiarities of the substratum.

To what extent does an addition of alcoholate change the velocity of the exchange in alcohol solutions? From Table 2 it is apparent that upon catalysis by In. alcoholate solution the exchange reactions proceed faster than with ammonia. This is not surprising, because the affinity of the ethoxy-ion to a proton in kilocalories is 50 times greater than the affinity of the ammonia molecule. Indirect comparison indicates that in the first group of substances (indene, acetophenone), in the presence of the  $\text{D}_5^2\text{O}$  ion, hydrogen exchanges by 4-6 times, and in groups of heterocycles (quinaldine, picoline) by 3 times, faster than in pure alcohol.

In experiments with alcohol solution of alcoholate (1 n.) for the first group of substances k is greater by 3-0.5 times than in experiments with ammonia, and in heterocycles the exchange proceeds with a speed four times. It is probable that this occurrence-analogous with non-identical change of dissociation constants of variously structured acids - is observed upon a change of the solvent. Numerous examples of similar departure from Brønsted theory

are described in works of N. A. Izmaylov /25/. Cases are known when the corresponding divergences between the constants of the acid dissociation reach up to an order of 6. The noted deviation from Brønsted theory was also stated by M. I. Kobachnik /28/ upon the occasion of examining regulations of tautomeric conversions.

Unexpected was the acid catalysis of the hydrogen exchange in indene by alcohol solution of DCl (at concentration of acid solution  $I_m$ .  $k = 1 \cdot 10^{-5}$  and without the catalyst  $k = 10^{-6}$ ,  $150^\circ$ ). Koizumi /29/ failed to observe the acceleration of the exchange with heavy water in the presence of DCl. Verification indicated that the hydrogen in the methyl group does not participate in the exchange reaction, catalyzed by acid: two atoms of deuterium, which were introduced into the molecule of indene upon catalysis with alcoholates in deuteroalcohol were unaffected after heating the substance with HCl solution in ordinary alcohol. In quinaldine, however, dissolved in deuteroalcohol, the acid and the base catalyze the exchange of the same atoms of hydrogen (methyl group), and at the same time specifically those atoms which exchange with deuteroammonium. This was substantiated by appropriate experiments.

A solution of  $KND_2$  in  $ND_3$  catalyzes the hydrogen exchange many times greater than the solution of alcoholate in alcohol and this is in conformity with greater proton affinity of  $ND_2$  and  $ND_3$  in comparison with  $C_2H_5O^-$  and  $C_2H_5OD$ . Let us illustrate this by an example of Ye. N. Zvyagintseva's experiments with quinaldine. As is known, the reactions of hydrogen exchange with  $C_2H_5OD$  and  $ND_3$  proceed with closely identical velocity ( $pK=6.2$  and  $7.2$ ) at  $120^\circ$ . Upon addition of a base to both solvents the exchange velocities are equal ( $pK = 4$ ) but in entirely dissimilar conditions:  $120^\circ$  for 0.1 n. solution of alcoholate in alcohol and  $-30^\circ$  for 0.02 n. solution of amide in ammonium. The factual concentration of amide ions is even much smaller, because this ion is neutralized by quinaldine according to the equation:

Let us cite another example, where the substance (naphthalene) is such a weak acid that its neutralization of the amide can be neglected. According to measurements by Ye. A. Izrailevich /30/, after heating a solution of naphthalene in liquid ND with deuterium concentrate close to 100% for the duration of 100 hrs at  $120^\circ$  the water of combustion of naphthalene contained less than 0.05 atom.  $\beta$  deuterium. Therefore,  $k_{128} < 10^{-9} \text{ sec}^{-1}$ . Upon

catalyzing with 0.01 n. of  $\text{KND}_2$  the velocity constant is expressed as follows:

$$k = 10^7 \cdot e^{-13800/RT}$$

Allowing that the velocity constant is proportional to the catalyster concentration, which is not exactly accurate, we find for In. solution  $\text{KND}_2 K=10^1$ . Therefore  $\text{KND}_2$  speeds up the reaction by at least 10 orders.

In consequence of very high catalytic action of potassium amide, the measurement of the exchange velocity can be achieved only in a comparatively narrow interval of concentration. With increase of the amide concentration from 0.01 to 0.43 n., the hydrogen exchange velocity in benzene (Table 3) increases only 23 times. It is proportional to amide concentration only in the area of low concentrations /30/:

Table 3  
Relationship between the hydrogen exchange velocity in benzene and the concentration of deutero-treated potassium amide.\*

$\text{KND}_2$ (n.)	0,01	0,014	0,021	0,039	1	0,19	0,43
$c/c_1$	1	1,4	2,1	5,9	19	43	
$k/k_1$	1	1,8	2,0	4,1	9,5	23	

\*  $c_1 = 0,01$  n.  $k_1 = 4,4 \cdot 10^{-5}$  cm.<sup>-2</sup> rpm 25°.

It appears that the lagging of K with increase of concentration is connected with considerable inter-ion interaction because of low DP (Diss. constant) of liquid ammonium and is due to formation of ion-pairs between  $\text{ND}_2^-$  and  $\text{K}^+$ . A similar concentration effect was noted earlier upon study of acid catalysis reactions of ammonolysis ammonium (see /31/, page 284).

A solution of  $\text{KNO}_2$  in  $\text{ND}_3$  so strongly catalyzes reactions of hydrogen exchange that Ye. A. Izrailevich accomplished partial hydrogen exchange in saturated hydrocarbons (Table 4). In truth, the experiments were continued at high temperature ( $110-120^\circ$ ) for hundreds of hours.

\*\*Experiments were conducted in ampullas of non-rusting steel. Therefore a catalytic effect of the container walls is not excluded. However, control experiment with methylcyclohexane, conducted in glass ampullas (with counter-pressure), marked with an asterisk, indicate that the isotope hydrogen exchange in saturated hydrocarbon proceeds upon

but the exchange was sufficiently measurable; 18% deuterium was introduced into the substance. In Table 4 the following designations are used:

$\tau$ -duration of experiment in hrs.

$c_{KN_2}$ -amide concentration (n.)

$c_p$ -concentration of deuterium in solvent.

$c_b$ -concentration of deuterium in the water of ignited substances (atom. %).

n-number of hydrogen atoms changed into deuterium.

There is a noticeable drop in the degree of the exchange with the increase of the catalyst up to 8n. This observation requires additional verification.

##### 5. COMPARISON OF VELOCITIES OF DEUTEROEXCHANGE WITH AMPHOTERIC AND PROTOGENIC SOLVENTS.

We shall try to estimate to what extent the exchange reaction is speeded up if instead of water we select various acid solvents and also use catalysts. According to Small

catalysis with potassium amide and in the absence of metal.

and Wolfden /32/, the heating of a phenol solution in heavy water at 100° causes exchange of two atoms of hydrogen of the aromatic ring after 400 hours; that is, taking into account three atoms of hydrogen. According to Koizumi /33/, in a 0.5 n solution of hydrochloric acid at 100° two atoms of hydrogen exchange every two hours ( $k=10^{-5}\text{ sec.}^{-1}$ ). A. V. Vedeneyev /34/ demonstrated that with liquid deuterium bromide, three atoms of hydrogen exchange immeasurably fast even at room temperature. Just as fast goes the reaction between DBr and anisole /34/ but, judging by Brown /11/ measurements, with icecold (glacial) acetic acid anisole does not exchange hydrogen upon heating to 90° for two days. Addition of sulfuric acid ( $\sim 0.1$  n. solution in glacial acetic acid) causes under the same conditions an exchange of more than two atoms of hydrogen /11/ (Table 5).

We shall conditionally accept for the reaction of the hydrogen exchange between  $C_6H_5OH$  and  $D_2O$   $\Delta H = 30$  kcal. and assume that the constant of the velocity exchange between  $C_6H_5OH$  and DBr is  $k < 5 \cdot 10^{-8} \text{ sec.}^{-1}$ . In this case, the velocity reactions in the two mentioned solvents differ by at least 6 to 8 orders.

Hydrogen exchange with liquid deuterium bromide is strongly catalyzed by aluminum bromide. At concentration  $\sim 10^{-3}$  mole  $AlBr_3$  on 1000 g. DBr the hydrogen of benzene exchanges immeasurably fast at room temperature and very fast at low temperature: during the time of cooling of the solution and evaporation of the solvent (5-7 min.) there is an equilibrium distribution of deuterium, corresponding to a temperature -50° -70° /35, 36/. In absence of a catalyst, the hydrogen in benzene exchanges with liquid DBr exceedingly slow:  $k = 5 \cdot 10^{-8} \text{ sec.}^{-1}$  at 20° /37/. Therefore, though the estimates appear to be very roughly approximate, it is clear that the hydrogen exchange velocities in organic substances with  $D_2O$  and  $AlBr_3$  in liquid DBr differ by no less than 20 orders. Catalysis by aluminum bromide is explained by

substratum. In this reaction no free ions are formed.

As a result of exceedingly high catalytic activity of aluminum bromide solution in liquid hydrogen bromide, there appeared to be a possibility of the occurrence of hydrogen exchange even in alicyclic hydrocarbons. Hydrogen exchange in cyclohexane was noted by Ya. M. Varshavskiy and S. E. Vaisberg /38, 39/; and K. I. Zhdanova, V. P. Kalinchenko and L. N. Vinogradov /35/ measured its velocity approximately. At  $c_{AlBr_3} = 10^{-2}$  mole/1000 DBr  $k \sim 10^{16} \text{ sec.}^{-1}$ .

The velocity exchange constant of the reaction is approximately proportional to the concentration of  $\text{AlBr}_3$ , hydrocarbons

with a tertiary atom of carbon exchange hydrogen with liquid DF in absence of catalyst (Table 6). The reaction velocity increases upon addition of  $\text{BF}_3$ , which, in liquid deuterium fluoride, is an acidic catalyst because it displaces the equilibrium of ionization of the solvent by adding an ion of fluorine:  $S + \text{DF} \rightleftharpoons \text{SD}^+ + \text{BF}_4^-$ .

Complex formation manifests itself by an increase of solubility of many substances, in coloring of the solutions.

Upon catalysis with  $\text{BF}_3$  (0.4 mol. 1000 g DF) there occurs an exchange even in a saturated hydrocarbon not possessing tertiary atom of carbon and nonisometric (cyclopentane) according to the available data. Therefore, in order to achieve hydrogen exchange between a saturated hydrocarbon and an acid, the presence of tertiary carbon

\*In liquid DF ionization occurs much easier than in DBr, but the free ions, probably, do not form in all cases.

atom and the presence of an oxidizer are not obligatory, but the acid catalysis is of importance.

Experiments were conducted by shaking in view of the poor solubility of the mentioned substances in liquid DF.

The comparisons presented in this report for reaction velocities of hydrogen exchange are extremely sketchy but they nevertheless give a descriptive notion of how much broader becomes the entire area of base-acid catalysis of hydrogen exchange when protophilic and protogenic solvents can be used instead of amphoteric.

#### 6. EFFECT OF DP AND POLARITY OF SOLVENT MOLECULES ON DEUTEROEXCHANGE.

Above we were engaged in a comparison of exchange reactions velocities in amphoteric solvents. On the basis of work by Ye. A. Yakovleva it is possible to say something about the indirect hydrogen exchange in various protophilic solvents - liquid deuteroammonia, anhydrous deutero-hydrazine, and anhydrous deutero-ethylene-diamine. The results of experiments (pk) with fluorene, tri-phenylmethane, quinaldine and di-phenyl-methane are presented in Table 7, from which it is clear that the velocity of exchange reactions with  $\text{N}_2\text{D}_4$  and  $\text{ND}_2\text{CH}_2\text{CH}_2\text{ND}_2$  are greater by 1-1.5 orders than with  $\text{ND}_3$ . The exchange with hydrozine proceeds faster than with ammonia despite the fact that tri-

Table 7  
Values pk at hydrogen exchange of some organic substances  
in various protophilic solvents.

1 Вещество	°C	2 Растворитель

phenyl-methane and diphenyl-methane-soluble in liquid ammonia are poorly soluble in hydrazine and the reaction proceeds in a heterogenous system (the pk values are placed in parentheses).

Let us turn to Table 1, characterizing the properties of solvents.

The dielectric constants of liquid ammonia and ethyl-diamine are almost identical, but the polarity of the second solvent molecule is greater and - if we judge by the values of its dissociation constant in water - it is a stronger base. It is probable that this is the reason for its faster exchange compared with ammonia.

Hydrazine is a weaker base than ammonia but its molecule is more polar and its DP is more than three times greater /52 and 16/. We are inclined to think that this fact is responsible for the speedier exchange with hydrazine and this is also noticed in experiments with sodium acetate.\*

As to the effect on the velocity of the hydrogen exchange of DP and the polarity of the solvent molecules, all that was successfully demonstrated by a comparison of kinetics exchange in two acid solvents - liquid hydrogen bromide and liquid hydrogen fluoride.

Ya. M. Varshavskiy and M. G. Lozhkina /41, 40/ measured the velocity of the hydrogen exchange reactions between benzene and liquid DF. The velocity appeared to be 4.3 times greater than the velocity with DBr. Sharp acceleration of exchange with DF was substantiated by experiments with tatuene, where the same degree of

\*Perhaps, the fact that the number of hydrogen atoms in molecules of the two last solvents is greater than in the molecule of ammonia (statistical factor) is of some importance.

exchange ( $n = 4.8$ ) was reached at  $20^\circ$  correspondingly after 6 and 90,000 min.

An observation of A. V. Vedeneyev and M. G. Lozhkina /34, 40/ is worth noting - the exchange of all atoms of phenol hydrogen and its esters in liquid deuterium fluoride, in contrast to the exchange of deuterium bromide, which is limited only to three hydrogen atoms of the aromatic rings. Therefore, with DF, the exchange proceeds easier than with DBr (see Table 5).

In the series of hydrogen halides, the acid properties increase from fluorine to iodine, and the hydrogen fluoride appears much less acidic than hydrogen bromide (see Table 1), but in the liquid state it has a DP 20 times greater than the DP of bromide (DP = 80 and 4 correspondingly). The DF molecule is more polar than the DBr molecule. These differences, we believe, are connected with the speeding up of the exchange reactions, when the substances are dissolved in DF.

## 7. EFFECT OF SUBSTRATUM CHARGE AND CATALIZER ON DEUTEROEXCHANGE.

Let us pause to consider the effect of catalyst and substratum charge on the velocity of the catalytic reactions in relation to DP solvent. This relationship was made apparent and proven experimentally by Bernsted on an example of a reaction-catalyzed by bases-of dissociation of nitroamide in water (DP = 80), m-cresole (DP = 13) and iso-amyl-alcohol (DP = 5.7) /see 42, 43, 2, 31/.

The relative velocities of dissociation in the named three solvents upon catalysis of the benzoate ion and the molecule of aniline are given in Table 8, from which it is clear that upon catalysis by ion of benzoate the velocity constants increase in the direction from water to m-cresole and to iso-amyl-alcohol, because polarization of the substratum molecule in the area of anion increased with decrease of DP of the solvent. On the contrary, upon catalysis by an electro-neutral molecule of aniline, the constants decrease with the same sequence; high DP contributes to proton transition from one electro-neutral molecule to another.

It is entirely natural that an analogous effect must also be observed with reactions of hydrogen exchange and at the same time it is possible to foresee that in the case of alkali-catalysis the negative charge of the substratum will retard the exchange reaction, catalyzed by a base, because it tends to impede the drawing off or breaking away of the proton. The negative charge of the catalyst interferes with the approach with the similarly charged substratum,

specially at low DP of the solvent /44, 12/. Upon acid catalysis, the retardation of the reaction will bring about a positive charge in the substratum because it will impede the junction of the deuterium to the substratum, which is a prerequisite to an exchange reaction.

Indeed, from Ye. A. Yakovleva /44/'s work it is apparent that the velocity of the hydrogen exchange in acetate ion with heavy water (DP = 80) and with deutero-ammonia (DP = 16) is almost identical and somewhat less than the velocity exchange in anhydrous deutero-hydrazine (DP = 52). The following values were obtained for pk: 7.2; 7.7; 6.5. There is hardly a difference ( $Pk_{120^\circ} = 4.4$  and 4.5) in constants of the velocity exchange at identical concentration of ions (1 n.)  $OD^-$  in  $D_2O$  and  $ND_2^-$  in  $ND_3$ , catalyzing the reactions. In order to make clear to what extent the charge of substratum influences the reaction velocity, catalyzed by ions  $ND_2^-$ , it is sufficient to recall that in the absence of a catalyster hydrogen exchange with liquid deutero-ammonia in the ion of acetate and in the molecule of quinalline proceeds at the same temperature ( $120^\circ$ ) and with almost the same velocity (pk = 7.7 and 7.2), but in order to achieve close velocity exchange (pk = 4.4 and 4) upon catalysis by potassium amide, it is necessary to conduct the reaction with the ion at  $120^\circ$  and  $c_{ND_2^-} = 1$  n., whereas reaction with the molecule proceeds at  $-30^\circ$  and  $c_{ND_2^-} < 0.02$  n.

The retardation of the exchange of reaction catalyzed by anions in the presence of a negatively charged substance is substantiated by A. V. Vedeneyev /34/. At a concentration of potassium amide, equal 0.4 n. and at  $50^\circ$ , the exchange of hydrogen in an ion of phenolate proceeds with a velocity smaller by 3 orders compared to benzene.

The retardation of the exchange reaction catalyzed by acid in the presence of a positive charge of the substratum was substantiated experimentally by comparing velocities of the hydrogen exchange reactions in aromatic hydrocarbons.

Hydrogen in anthracene exchanges with liquid DBr 5-6 times faster than in benzene /37/. Knowing that the reaction velocity of the hydrogen exchange between benzene and DF is greater by 4.3 orders than with DBr, it is natural to expect that the exchange between anthracene and deuterium fluoride would proceed immeasurably fast. However, it appeared /40/ that hydrogen in anthracene exchanges with DF at least by one order slower than the reaction of the hydrogen exchange taking place between benzene and DF.

The presented facts are easily explained if we remember the strong ionization of anthracene dissolved in

Table 8  
Velocity of catalytic dissociation of nitramide in various solvents.

liquid HF, which was indicated by Klatt's /45/ measurements of electroconductivity and boiling temperature of solvents. A proton (or deuteron) joins a molecule of anthracene almost exclusively in the meso-position /40/. Therefore, the exchange of meso-atoms proceeds rapidly and the exchange of the remaining atoms of hydrogen in ion (C<sub>14</sub>H<sub>10</sub>D)<sup>+</sup> is impeded.\*

According to Reid /47/, the addition of BF results in full ionization of anthracene in liquid HF<sub>3</sub>. Therefore, in agreement with the presented treatise, the presence of BF, not only does not increase but actually decreases the isotope exchange of hydrogen in anthracene by limiting the exchange only to two atoms. For example, in a solution containing BF<sub>3</sub> (0.4 mole/1000 g DF), after 2 hours 2 atoms of hydrogen are exchanged (meso-atoms), but without BF, during the same time, an exchange of 9 atoms is achieved, whereas in benzene with catalyst after one half hour 5 atoms are exchanged and in the presence of BF<sub>3</sub> (0.1 mole/1000 g DF) a complete exchange of hydrogen occurs in less than 2 minutes.

In increase of the number of condensed rings leads to an increase of strength of the aromatic hydrocarbons as bases /14/ and to heightening the degree of their ionization in DF /48/ /45/. Correspondingly (Table 9), the velocity

M. I. Kabachnik called our attention to the fact that the condition for this is a retardation of the anthracene ionization.

Besides electrostatic action of the charge during the exchange reaction, the change in the distribution of the electron density in molecule of the substance, which is caused by ionization, is important.

of the hydrogen exchange, catalyzed by  $\text{BF}_3$ , decreases in sequence benzene > naphthalene > anthracene.

Table 9

Velocity of the hydrogen exchange catalyzed by boron-fluoride in benzene, naphthalene and antracene.

1 Вещество	2 Концентрация $\text{BF}_3$ , мол./1000 г DF	3 t, мин.	4 % обмена
5 Бензол	0,1	2	100
6 Напthalен	0,2	6	80
7 Антрацен	0,4	120	20

1-substance; 2-concentration  $\text{BF}_3$  mole/1000 g DF; 3- min.;  
4- % exchange; 5- benzene; 6-naphthalene; 7-anthracene.

At the same time on dissolving in liquid DBr., - that is, when in view of the low DP of the solvent ionization has no essential value, and in the exchange reaction, there participate electro-neutral molecules of hydrocarbons - the exchange is accelerated with the same sequence: benzene < naphthalene < anthracene /49/. This depends on the fact that the stronger the base the easier is the occurrence of deuteron transfer to a molecule of hydrocarbon, which - as was noted above - is the necessary stage of the hydrogen exchange reaction with acid.

Thus one and the same cause - acid-base interaction with aromatic hydrocarbon, having non-equivalent hydrogen atoms - may lead -depending on the conditions of the flow of the reaction - to diametrically opposite consequences: to the reversal of the order of the relative velocity reactions of the hydrogen exchange.

Thus, we are convinced that besides protophilic and protogenic properties of the solvent and the catalyst, which of course exert great influence during the hydrogen exchange reactions it is necessary to take into account at least the following parameters: structural peculiarities and the charge of the substratum and the catalyst; and DP of the solvent and the polarity of its molecule. These parameters permit a change of the hydrogen exchange velocity: faster exchange may occur in a solvent less basic or less acid; it is possible to retard the exchange despite greater protophilic or protogenic properties of the reagents. Therefore, a comparison of the velocities of hydrogen exchange reactions, without consideration of other circumstances, may lead to erroneous conclusion as to relative

cidity or alkalinity of substances. The best confirmation of this is the fact of reversal of the sequence of the velocity of the hydrogen exchange of aromatic hydrocarbons, regarding which the above story was related.

### 8. PARTICIPATION OF SOLVENT IN CATALYTIC EXCHANGE

Unquestionably, the exchange reaction is connected with proton (or deuteron) transition from substratum to catalyst or from catalyst to substratum, while a complete transition is not obligatory. Undoubtedly, participation of solvent in the exchange reaction is of importance. This is apparent from the fact that though the ion  $C_2H_5O^-$  is deprived of deuterium the isotope exchange occurs, and it is clear that it is caused expressly by the  $C_2H_5O^-$  ion, because otherwise the latter would not be able to perform the function of catalyst. It follows that the solvent participates in the reaction. Therefore, it is of interest to know how, with the same substratum and catalyst, the velocity of the reaction changes with the change of the solvent, its peculiarities, properties, constants. This question is as yet insufficiently illuminated and its exploitation may result in introducing new understanding of the exchange mechanism. It is necessary, of course, to remember that sometimes under the influence of solvent, the catalyst may change; for instance, in an excess of alcohol, the hydroxyl-ion turns into a ethoxy-ion /23/.

Ye. A. Vakovleva and Ye. N. Zvagitseva obtained some facts relative to hydrogen exchange catalysis in methenyl group of tri-phenyl-methane by  $C_2H_5O^-$  ion in ethyl alcohol and ethyline-diamine and by the  $NH_2C_2H_4O^-$  ion in ethyline-diamine and ethanolamine. It was found that though at a concentration of  $C_2H_5O^-$  in alcohol equal to 1 n. and of  $NH_2C_2H_4O^-$  in ethanolamine equal to 0.1 n., the constants of the velocity exchange reactions are equal correspondingly to  $3 \cdot 10^{-5}$  and  $2 \cdot 10^{-5}$  sec.<sup>-1</sup> at 120°, the same catalysts dissolved in anhydrous ethylenediamine at concentrations less than 0.1 n. lead to complete exchange of the methenyl hydrogen of tri-phethyl-methane after 15 min. at temperature 25°. The work continues.

### 9. CATALYTIC ISOMERIZATION OF HYDROCARBONS.

Acid-base catalysis of the hydrogen exchange sometime is accompanied by catalysis of the hydrocarbon isomerization. The presence of isomerization is evident through the change

of constants and the appearance of new frequencies in the substance's spectral oscillations. Table 10 gives some examples of hydrocarbon isomerizations, catalyzed by solutions of potassium amide in liquid ammonia (N. M. Dykhno, L. N. Vasileva, see /50/, also /51/) and tri-fluoride boron in liquid hydroge fluoride (Ya. M. Varshavskiy, M. G. Lozhkina).

After treatment of cyclohexane with aluminum bromide

in liquid hydrogen bromide, there appears a band with frequency  $890 \text{ cm}^{-1}$  in the spectrum of the combined dispersion of the hydrocarbon which is typical for methylcyclopentane /see 35/.

Isomerization of hydrocarbons accompanying reactions of hydrogen exchange in the noted solvents upon action of the named catalysts is as yet insufficiently studied and the specific role which is played by it is not clear. For instance, in order to explain how complete hydrogen exchange is achieved in ethylene hydrocarbons with a long chain of carbon atoms and a double bond at the beginning or in alicyclic hydrocarbons with a double bond in side chain, it is necessary to admit that the potassium amide causes migration of the double bond along the chain of the carbon atom and from the side chain to the cycle /50, 52/. It is possible that the hydrogen exchange in cyclohexane with liquid DBr in presence of  $\text{AlBr}_3$  and with liquid DF at catalysis of  $\text{BF}_3$  is favored by the equilibrium isomerization in methylcyclohexane. In the nearest future it will be necessary to establish the velocity ratio between the isomerization reactions and the hydrogen exchange.

#### 10. CONCLUSION

In this report, the question of acid-base catalysis of hydrogen exchange reactions was discussed. The very fact of such catalysis speaks first of all of the fact that hydrogen exchange is actually caused by acid-base interaction - a thesis in the foundation of which the Isotope Reactions Laboratory was actively participating. The majority of the parameters which influence velocity of hydrogen exchange reactions were visualized on the basis of the existing theory of acid-base equilibrium and catalysis of Bernsted. These parameters were made distinctly apparent in works summarized in the report. Moreover, it is now clear that the Bernsted theory only approximately describes acid-base processes, because the latter do not necessarily amount to simple proton transition. For further development of the theory, an accumulation of new experimental material will be of assistance.

Though in this report, dedicated to catalysis of the hydrogen exchange, little was said relative to the mechanism of the process, it is obvious that this question is impossible to discuss without consideration of the laws of acid-base catalysis of exchange reactions.
